Infectious Disease Review

An Overview of Publications Featuring Illumina technology

Table of Contents

Introduction

The new generation of sequencing technology[1,2] is an extraordinary powerful set of tools that is opening the door to improved diagnosis and treatment of infectious diseases.[3,4] Whole-genome next-generation sequencing can both detect and identify infections agents in one assay without any prior knowledge of the clinical presentation. The same assay will also provide information about the antibiotic resistance, virulence and origin of the infectious agent. A universal test for all microbes provides a simplified and uniform laboratory workflow that is objective, independent of the skill of the operator and can readily be validated and controlled.[5] A more accurate diagnosis and treatment will lead to reduced hospital stays and the more considered use of antibiotics, but the ultimate beneficiary will be the patient who will benefit from the improved level of care.

This document is intended to highlight recent publications that demonstrate the application and potential of next-generation sequencing technologies to detect and control of infectious agents.

General Reviews

The following reviews offer a useful introduction to the topic

Didelot, X., Bowden R., Wilson D. J., Peto T. E. and Crook D. W. (2012) Transforming clinical microbiology with bacterial genome sequencing. Nat Rev Genet 13: 601-612

The authors compare the current practices of identifying and typing bacteria to a workflow based on next-generation sequencing. They predict that the application of next-generation sequencing will soon be sufficiently fast, accurate and cheap to be used in routine clinical microbiology practice. It could replace many complex techniques currently used in clinical microbiology practice with a single, more efficient workflow. The review goes on to discuss the changes that will be required in the organization, skill mix and infrastructure of diagnostic laboratories to adopt this technology.

Pathogen Identification

Traditional microbial identification relies on clinical symptoms and some prior knowledge to identify microorganisms. Some cases are atypical and defy identification. With the increase in international travel obscure tropical diseases can appear in unlikely places. To complicate the matter further some organisms are still unknown and many cannot be cultured in the laboratory. In some cases the organism can escape detection altogether.[6] Next-generation sequencing interrogates the genome directly and can detect and identify completely novel, uncultured organisms and at the same time derive information about their epidemiology and biology, such as virulence and antibiotic resistance.[7]

Sequencing does not require prior knowledge to identify microorganisms.

Some autoimmune diseases and several types of cancer are associated with pathogens. This study is a proof of principle to determine the detection level of viral transcripts through RNA-seq libraries spiked with decreasing amounts of an RNA-virus. The authors find that viral transcripts can be detected at frequencies less than 1 in 1,000,000 even at a modest depth of sequencing. This shows that NGS is a highly sensitive method for detecting putative infectious agents associated with human tissues.

A recent case of melioidosis in non-endemic Arizona was determined to be the result of locally acquired infection, as the patient had no travel history to endemic regions and no previous history of disease. Diagnosis of the case was confirmed through multiple microbiologic and molecular techniques. This is a nice example of sequencing to identify a pathogen.

Virus Identification

The ambiguous symptoms of viral infections make them a diagnostic challenge. In addition their genetic nimbleness[8] and stringent culture requirements have made them a challenge to identify. Recent studies demonstrate the ability of next-generation sequencing to detect and identify viruses that have escaped detection by standard techniques.[9] This capability has led to new interest in searching for viral infections in tumors[10] and chronic diseases.[11]

The combination of high sensitivity without the need for prior information will make next-generation sequencing the primary tool for viral detection and identification.

The authors analyzed 176 nasopharyngeal swabs and plasma samples from children with unidentified fever and afebrile controls. They identified of sequences from 25 viral genera, including expected pathogens, such as adenoviruses, enteroviruses, and roseoloviruses, plus viruses with unknown pathogenicity. Differences between febrile and afebrile groups were most striking in the plasma samples, where detection of viral sequence may be associated with a disseminated infection. These data indicate that virus infection is associated with unidentified fever.

The authors used deep sequencing to detect virus sequence in 37% (45/123) of previously negative cases. These included 13 cases with Human Herpesvirus 6 sequences. Other samples contained sequences with similarity to sequences from viruses in the Herpesviridae, Flaviviridae, Circoviridae, Anelloviridae, Asfarviridae, and Parvoviridae families. In some cases, the putative viral sequences were virtually identical to known viruses, and in others they diverged, suggesting that they may derive from novel viruses. By contrast the Virochip analysis produced putative viral hits in 10/123 (8%) of the previously negative samples. These results demonstrate the utility of unbiased approaches in the detection of known and divergent viruses in the study of tropical febrile illness.

The authors demonstrate that they can robustly detect mutations at 0.1% fractional representation. This represents accurate detection of one mutant per every 1000 wild-type alleles. The method for detecting rare variants compares the baseline error rate from multiple reference replicates to the sample error rate at each position. To demonstrate the utility of the method they analyzed nine clinical samples of H1N1 influenza A and detected an oseltamivir (antiviral therapy) resistance mutation in the H1N1 neuraminidase gene at a sample fraction of 0.18%.

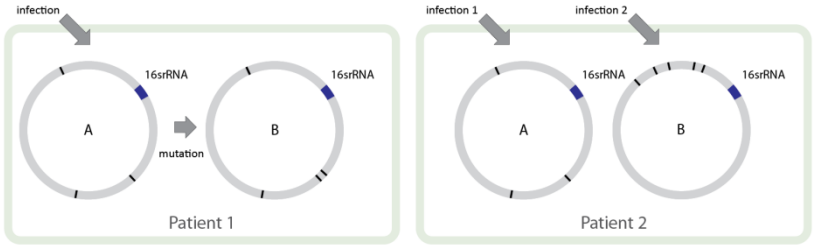
Multiple- and Chronic Infections

Recurring infectious disease can be challenging to manage if the underlying cause is unknown.[12] Is the recurring disease due to a reservoir of untreated microbes in the patient or was the patient exposed to an external source of infection? The answer to this question will fundamentally change how the patient will be treated and the infection controlled.

In the course of an infection microbes acquire mutations as they adapt to the host responses and clinical interventions,[13] such as the development of antibiotic resistance during a chronic infection.[14] As a result naturally acquired infections can consist of several clones. Alternatively clones may also represent recurring infections.[15] Next generation sequencing provides a high resolution map of the microbe that can easily distinguish between those two possibilities.[16] The microbial sequence also provides insight in the development of antibiotic resistance and virulence.[17]



In patient 1 a single infection may lead to two clonal types due to evolution of the microbe. These clones may be highly similar and vary by as little as a single nucleotide mutation anywhere in the genome. In patient 2 there are several unrelated differences between the clones. This may be due to multiple infections. Multiple clones are of clinical interest for infection control

Some important human pathogens, both Gram positive and negative, can undergo transformation.[18] Genetic transformation is the process by which cells take up DNA from the environment and integrate the sequence into their genome.[19] Transformation is a clinically important mechanism because it allows bacteria to rapidly adapt in response to clinical interventions; examples include facilitating vaccine evasion and the development of penicillin resistance in the major respiratory pathogen Streptococcus pneumoniae.[20]

Clones are of clinical interest as they may harbor drug resistance genes that may lead to enhanced survival of the resistant clone after treatment and the possibility of subsequent therapeutic failure.

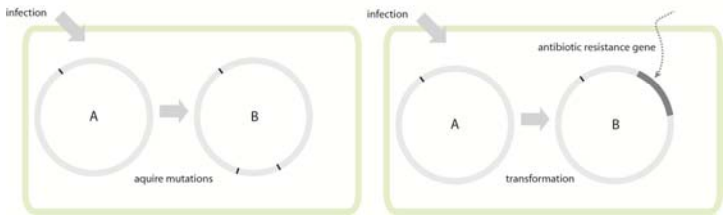
Current approaches require prior knowledge of the markers that can identify each clone and PCR frequently fail to detect low-abundance clones.



In patient 1 a single infection may progressively acquire mutations in response to clinical intervention. These clones may be highly similar and vary by as little as a single nucleotide mutation anywhere in the genome. In patient 2 the microbe actively acquires antibiotic resistance or virulence genes from donors in the environment. The process allows rapid changes in drug resistance or virulence.

The authors sequenced 5 non-propagated Plasmodium falciparum parasite isolates taken directly from 4 different patients treated for clinical malaria. The sequenced isolates contained both known and novel gene deletions and amplifications. Genome-wide analysis of clone multiplicity revealed that each patient harbored at least 3 clones of P. falciparum by this analysis. This demonstrates that genome sequencing of peripheral blood P. falciparum taken directly from malaria patients provides high quality data useful for drug resistance studies, genomic structural analyses and population genetics, and also robustly represents clonal multiplicity.

Antibiotic Resistance and Virulence

Antibiotic resistance is a serious consequence of evolutionary pressure in a bacterial population. Serotyping is commonly used as a marker for virulence. However, there is little or no functional connection between the genes that encode the bacterial capsule to determine the serotype and the genes associated with antibiotic resistance. The bacteria can change its capsule while retaining its virulence and antibiotic resistance.[22] Next-generation sequencing is proving to be a powerful tool to track the evolution of antibiotic resistance and virulence.

Four paper discs containing different antibiotics are placed on to a thin layer of Staphylococcus aureus bacteria in a Petri dish. The effects of antibiotic become visible by producing a reacting zone free of bacterial growth around the disc.

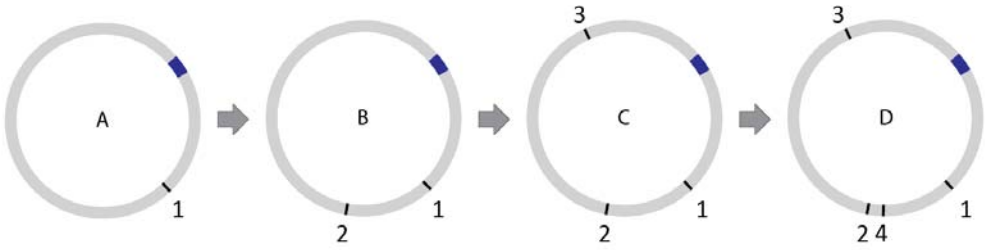
Epidemics and Transmission

Epidemics and microbial transmission have traditionally been tracked with serological or other markers that monitor only a small, arbitrary part of the microbial genome. Due to the mosaic nature of the microbial genome any approach that monitors only a part of the genome will be relatively unreliable and insensitive. By contrast next-generation sequencing can track every base in the genome, which has led to a revolution in our understanding of these processes.[23,24] Transmission can now be tracked over relatively short periods of time even within families[25] or hospitals[26] and the source of the outbreak can be determined.[27,28,29] This allows a much more rapid and targeted response to outbreaks.[30] An additional benefit is that the mutations that accumulate during an outbreak can provide information about the potential development of antibiotic resistance and changes in virulence.[31,32]



As microbes accumulate mutations it is possible to track the sequence of transmission. The numbers indicate the addition of mutations in this hypothetical case. To track transmission events over short periods of time, such as weeks, the sequencing technology must be able to detect, with confidence, single base mutations anywhere in the genome.

The authors successfully sequenced and analysed 26 MRSA and 15 C difficile isolates within 5 days of culture. Both MRSA clusters were identified as outbreaks, with most sequences in each cluster indistinguishable and all within three single nucleotide variants (SNVs). Epidemiologically unrelated isolates of the same spa-type were genetically distinct (≥21 SNVs). In both C difficile clusters, closely epidemiologically linked cases (in one case sharing the same strain type) were shown to be genetically distinct (≥144 SNVs). A reconstruction applying rapid sequencing in C difficile surveillance provided early outbreak detection and identified previously undetected probable community transmission. A useful observation in this study is that the same technology and procedures can be used regardless of microbe.

An outbreak of M. tuberculosis in British Columbia in 2006 demonstrates how sequencing can be used to unravel a complex epidemic. When the results of mycobacterial interspersed repetitive unit–variable-number tandem-repeat (MIRU-VNTR) genotyping and traditional contact tracing failed to identify a source of the M. tuberculosis epidemic, the authors used whole-genome sequencing and social-network analysis to describe the outbreak dynamics at a higher resolution. To do this, they used an Illumina Genome Analyzer II to sequence a total of 36 M. tuberculosis isolates (32 of the 37 outbreak isolates and 4 historical isolates with identical MIRU-VNTR patterns). This yielded an average of 99.21% of the reference genome being covered by at least one 50bp read. The higher-resolution SNP patterns afforded by whole-genome sequencing revealed that the outbreak was the coalescence of two outbreaks, each with its own causative lineage of M. tuberculosis. The simultaneous reappearance of two extant lineages suggests that a social or environmental factor, not a genetic change in the organism, most likely triggered the outbreak. A rise in crack cocaine use that peaked within the community at the outbreak of the epidemic may have been this trigger.
